Submitted 26 October 2010

Formation of stable domains filled with strongly correlated coherent quark matter is discussed in general terms and is exemplified further in the framework of the Generalised Nambu–Jona-Lasinio model. It is argued that such domains, if exist in the Universe, appear dark to an external observer.

1. Introduction. The QCD vacuum is known to be a highly nontrivial medium consisting of fluctuations of gluonic fields, various condensates, and so on. One of the best studied and microscopically understood phenomena related to these nontrivial properties of the vacuum is the spontaneous breaking of chiral symmetry – a global symmetry inherent to the QCD Hamiltonian, which, however, is not respected by its lowest eigenstate, that is by the vacuum. As a result, the entire tower of hadronic states built on top of the vacuum lacks this kind of symmetry as well. While the effect of spontaneous chiral symmetry breaking is expected to play no role for highly excited states in the spectrum of hadrons – the so-called effective chiral restoration for highly excited hadrons (see review [1] and references therein) – the spectrum of low-lying states is strongly affected by chiral symmetry breaking. The most prominent example of the manifestation of chiral symmetry breaking in the spectrum of hadrons is provided by the pion, which plays the role of the pseudo-Goldstone boson associated with chiral symmetry breaking. Another manifestation of chiral symmetry breaking is given by the constituent mass, of the order of a few hundred MeV, which a light quark acquires in the course of its propagation through the vacuum.

The phenomenon of chiral symmetry breaking is a highly nonlinear effect, which is described in terms of nonlinear gap equations, often referred to as mass-gap equations. Such equations are known to possess at least two solutions – the trivial solution for the chirally symmetric vacuum $|0\rangle_0$ and a nontrivial solution describing the physical chirally nonsymmetric vacuum $|0\rangle$. In this Letter, we discuss in general terms a physical picture which can arise from a possible existence of further nontrivial solutions to the mass-gap equation – the so-called replicas. The existence of such solutions was emphasised many times in the framework of the Generalised Nambu–Jona-Lasinio model (GNJL). In particular, this was done in Ref. [2] for the quadratic confining

potential, in Ref. [3, 4] for the linear potential, and in Ref. [5] for an arbitrary power-like confining potential. In Ref. [6], similar solutions were considered in different approaches, while general arguments in favour of the existence of replicas were given in a recent paper [7]. For the sake of simplicity, we will assume throughout the present paper that only one such excited solution to the mass-gap equation exists, which will be denoted as $|R\rangle$. Once this is the case, the corresponding state possesses the energy density higher than that of the vacuum $|0\rangle$. However, since chiral symmetry is broken in the state $|R\rangle$, the latter is still energetically more preferable than the trivial, chirally-symmetric, vacuum $|0\rangle_0$. Below, it is assumed that such a replica state fills a finite-size domain in the Universe, and the problem of stability of such a domain is addressed. We start with a qualitative model-independent consideration, exemplifying it further by explicit calculations in the GNJL framework.

A replica-filled domain at issue is described by just two parameters – its radius R (the volume being denoted as V) and the momentum scale Λ_χ determining the characteristic distance R_χ at which chiral symmetry breaking occurs: $R_\chi \simeq 1/\Lambda_\chi \sim 1 \div 1.5$ fm. Indeed, it is legitimate to define Λ_χ in this way because the impact of chiral symmetry breaking is significantly weaker inside the domain than in the outer space, which is filled with the unexcited vacuum. For this reason, we can identify Λ_χ with a typical momentum scale of chiral symmetry breaking in the true QCD vacuum. As such, its value can be estimated as $250 \div 300$ MeV. Accordingly, the replica energy density relative to that of the unexcited vacuum appears as $\varepsilon = (\Lambda_\chi)^4 > 0$.

Below we impose constraints on the values of R , which ensure stability of the replica-filled domain.

2. A microscopic content of the excited vacuum state. In the true QCD vacuum, spontaneous breaking of chiral symmetry leads to the formation of the chiral condensate – a coherent-like state of strongly correlated 3P_0 quark–antiquark pairs. Being yet another

genuine solution to the mass-gap equation, the excited state $|R\rangle$ admits a similar microscopic interpretation. However, the way quark–antiquark pairs there get correlated to form the condensate is different – while the quantum numbers 3P_0 are obviously the same, in order to ensure the state $|R\rangle$ to be a scalar, the radial wave functions of such pairs appear to be excited. Clearly, while in the infinite-volume limit, the $|0\rangle$ and the $|R\rangle$ states are strictly orthogonal, for finite volumes V their overlap is nonvanishing and reads:

$$\langle 0|R\rangle = e^{-\Lambda_\chi^3 V}. \quad (1)$$

Below, by means of the explicit expressions found in the GNJL model, we represent Eq. (1) in terms of the chiral angle characterising a given replica $|R\rangle$.

Thus, we conclude that, from the viewpoint of an external observer, the replica-filled domain is nothing but a localised in space coherent cloud of strongly correlated quark–antiquark pairs.

3. Decays of the replica state and the minimal size of the domain. We are now in a position to estimate the minimal possible size of a stable replica-filled domain. Indeed, Eq. (1) suggests that the overlap between the replica and the vacuum increases as the volume of the domain decreases. Accordingly, the lifetime of the domain decreases fast with the decrease of its volume. To quantify this effect, one can use the Schrödinger equation for the domain of volume V ,

$$i\frac{\partial}{\partial t}|R\rangle = \hat{\mathcal{H}}|R\rangle, \quad (2)$$

where $\hat{\mathcal{H}}$ is the QCD Hamiltonian. Namely, we notice that: (i) if the excited state $|R\rangle$ decays into the unexcited one, $|0\rangle$, during the time τ , the derivative on the left-hand side of Eq. (2) can be approximately substituted by a finite difference, $\partial|R\rangle/\partial t \rightarrow (|0\rangle - |R\rangle)/\tau$; (ii) for a sufficiently large volume V , $|R\rangle$ is an approximate eigenstate of the Hamiltonian with the eigenenergy $V\varepsilon$. Temperature-dependent hadronic contributions to the energy density [8] can be shown to be negligible as compared to ε , up to temperatures ~ 25 MeV [7].

Finally, projecting Eq. (2) onto the vacuum state $|0\rangle$, using Eq. (1) and the fact that this state is normalised as $\langle 0|0\rangle = 1$, one arrives at the following estimate:

$$\tau^{-1} \sim V\varepsilon e^{-\Lambda_\chi^3 V} \sim V\Lambda_\chi^4 e^{-\Lambda_\chi^3 V}. \quad (3)$$

Thus, we find that the lifetime of the replica-filled domain can be estimated as

$$\tau \sim \frac{1}{\Lambda_\chi} \left[\frac{e^{\Lambda_\chi^3 V}}{\Lambda_\chi^3 V} \right]. \quad (4)$$

The condition of stability is obviously formulated as the requirement that τ is larger than the age of the Universe, $\tau > T_U$, that is

$$\frac{e^{\Lambda_\chi^3 V}}{\Lambda_\chi^3 V} > \Lambda_\chi T_U, \quad (5)$$

which yields an estimate for the volume of the domain in terms of the dimensionless parameter $\Lambda_\chi T_U$.

For $\Lambda_\chi T_U \gg 1$, relation (5) can be approximately resolved with respect to the volume as

$$V > \Lambda_\chi^{-3} \ln[\Lambda_\chi T_U \ln(\Lambda_\chi T_U)], \quad (6)$$

which gives for the minimal radius of the domain the value

$$R_{\min} = \Lambda_\chi^{-1} (\ln[\Lambda_\chi T_U \ln(\Lambda_\chi T_U)])^{1/3} \quad (7)$$

or, numerically,

$$R_{\min} \simeq 5 \text{ fm}. \quad (8)$$

Notice that, because of the weak logarithmic, further weakened by the cubic root, dependence of the result (7) on $\Lambda_\chi T_U$, the estimate (8) is very stable against variations of the values of both Λ_χ and T_U . The obtained estimate for R_{\min} is of the order of a typical nucleus size.

4. The maximum size of the domain compatible with its gravitational stability. In this section, we estimate the maximal possible size of the replica-filled domain. The existence of such an upper bound for the domain size is a necessary condition for the stability of the domain against the gravitational collapse [7]. Indeed, for a constant energy density ε at issue, the mass of a replica-filled domain increases linearly with its volume. Therefore, the Schwarzschild radius $r_g = 2G \cdot (V\varepsilon)$, where G is the gravitational constant, increases with the size of the domain as

$$r_g \propto R^3. \quad (9)$$

The gravitational stability condition requires that $r_g < R$, which leads to an estimate

$$R_{\max} \sim 1/\sqrt{\varepsilon G}. \quad (10)$$

For a more rigorous analysis, one can apply the Tolman–Oppenheimer–Volkoff (TOV) equation for the pressure inside a spherically-symmetric domain [7], and use its well-known solution for the case of a constant energy density [9]. It yields a more restrictive upper bound

$$R_{\max} = 1/\sqrt{3\pi G \Lambda_\chi^4} \sim 10 \text{ km}. \quad (11)$$

Notice that the obtained estimate for the maximum radius is of the order of a typical radius of a neutron star, which is also about 10 km.

A comment is in order here on a possible back reaction of the gravitational field of the domain on the equation of state (EoS) $\varepsilon = (\Lambda_\chi)^4$. Indeed, solving the TOV equation together with the EoS, one finds a solution which defines unambiguously the gravitational metric inside the domain (cf. Ref. [7]). The chiral condensate in such a curved space differs, generally speaking, from its flat-space counterpart, whose value was initially used in the EoS. Correcting the EoS accordingly and plugging it again into the TOV equation, one arrives at an iterative procedure. Fortunately, it turns out that, owing to the numerical smallness of the corresponding gravitational correction to the chiral condensate, the iterations terminate already at the zeroth one, that is the EoS and the mass-gap equation decouple from each other. Namely, the corrected chiral condensate has the form [7]:

$$\langle \bar{\psi}\psi \rangle = \langle \bar{\psi}\psi \rangle_0 [1 + \mathcal{O}((R_\chi/R)^2)]. \quad (12)$$

This result shows that, since chiral symmetry breaking and gravity are effective at different length scales, the equations describing them can be clearly separated. In particular, one can see that, even for a domain of the smallest possible size (7), the impact of its gravitational field on the chiral condensate is negligible.

5. Replicas within the GNJL. One of the most successful models in studies of various phenomena related to chiral symmetry breaking is the famous Nambu–Jona-Lasinio (NJL) model [10]. This model still possesses a few shortcomings, among which the most essential ones are the absence of an intrinsic scale, that shows up in the ultraviolet regularisation of the loop integrals, and the absence of confinement. A generalisation of the NJL model was suggested in Refs. [2, 11, 12] with the purpose to include confinement, that resulted in the proposition of the GNJL. Finally, the direct connection between the 3P_0 quark content of the vacuum – in terms of the chiral angle $\varphi_{\mathbf{p}}$ (see below) – and the mechanism for the spontaneous breaking of chiral symmetry was shown explicitly in Ref. [12].

The Hamiltonian of the GNJL reads:

$$H = \int d^3x \bar{\psi}(\mathbf{x}, t) (-i\boldsymbol{\gamma} \cdot \nabla + m) \psi(\mathbf{x}, t) + \frac{1}{2} \int d^3x d^3y J_\mu^a(\mathbf{x}, t) K_{\mu\nu}(\mathbf{x} - \mathbf{y}) J_\nu^a(\mathbf{y}, t), \quad (13)$$

where $J_\mu^a(\mathbf{x}, t) = \bar{\psi}(\mathbf{x}, t) \gamma_\mu \frac{\lambda^a}{2} \psi(\mathbf{x}, t)$, and $\psi(\mathbf{x}, t)$ is the quark field. Thus, the interquark interaction is parametrised by the quark kernel $K_{\mu\nu}$ which contains confinement explicitly, in the form of a rising potential.

The latter can be supplied with various extra terms, for instance the perturbative Coulombic one. The confining interaction between quarks brings a nonperturbative scale into the problem and models radial excitations of 3P_0 pairs mentioned above, in Sect. 2. Chiral symmetry breaking can then be described by the summation of loop diagrams for valence quarks (which leads to the mass-gap equation), while mesons are obtained from the Bethe–Salpeter equation for the quark–antiquark bound states. Besides that, GNJL is known to fulfil the low-energy theorems of Gell-Mann, Oakes, and Renner [13], Goldberger and Treiman [14], Adler self-consistency zero [15], the Weinberg theorem [16], and several others. We would like to emphasise a universal nature of the above low-energy theorems, regardless of a particular form of gluonic interactions which result in a chiral-symmetry-breaking quark kernel. Consequently, irrespectively of a particular form of the *confining* kernel $K_{\mu\nu}$, GNJL provides a reliable phenomenological approach to chiral symmetry breaking, which incorporates effects of confinement. Thus, owing to the fact that neither qualitative nor quantitative predictions of the GNJL depend on a particular form of $K_{\mu\nu}$, it suffices to impose this kernel to be confining and to introduce the scale of chiral symmetry breaking, Λ_χ .

Furthermore, all possible quark–quark interactions described by the Hamiltonian (13) include quark self-interactions. These self-interactions can be eliminated by the use of an appropriate Bogoliubov–Valatin transformation from bare quarks to the dressed ones. Such a transformation can be conveniently parametrised by means of the so-called chiral angle $\varphi_{\mathbf{p}}$ (\mathbf{p} being the relative momentum of a dressed quark–antiquark pair) [11, 12]:

$$\begin{aligned} \psi^\alpha(\mathbf{x}) &= \sum_{\mathbf{p}, s} e^{i\mathbf{p}\mathbf{x}} [b_{\mathbf{p}s}^\alpha u_s(\mathbf{p}) + d_{\mathbf{p}s}^{\alpha\dagger} v_s(-\mathbf{p})], \\ u(\mathbf{p}) &= \frac{1}{\sqrt{2}} \left[\sqrt{1 + \sin \varphi_{\mathbf{p}}} + (\boldsymbol{\alpha}\hat{\mathbf{p}}) \sqrt{1 - \sin \varphi_{\mathbf{p}}} \right] u_0(\mathbf{p}), \\ v(-\mathbf{p}) &= \frac{1}{\sqrt{2}} \left[\sqrt{1 + \sin \varphi_{\mathbf{p}}} - (\boldsymbol{\alpha}\hat{\mathbf{p}}) \sqrt{1 - \sin \varphi_{\mathbf{p}}} \right] v_0(-\mathbf{p}), \end{aligned}$$

where α is the colour index of N_C colours. It is convenient to define the chiral angle varying in the range $-\pi/2 < \varphi_{\mathbf{p}} \leq \pi/2$ and respecting the boundary conditions:

$$\varphi_{\mathbf{p}}(\mathbf{p} = 0) = \pi/2, \quad \varphi_{\mathbf{p}}(|\mathbf{p}| \rightarrow \infty) \rightarrow 0. \quad (14)$$

The normal-ordered Hamiltonian (13) takes the form:

$$H = E_{\text{vac}} + : H_2 : + : H_4 :, \quad (15)$$

and the usual procedure to minimise the vacuum energy E_{vac} is to set the quadratic part $:H_2:$ to be diagonal. Then the corresponding mass-gap equation,

$$\delta E_{\text{vac}}[\varphi]/\delta\varphi_{\mathbf{p}} = 0, \quad E_{\text{vac}}[\varphi] = \langle 0[\varphi]|H|0[\varphi]\rangle, \quad (16)$$

ensures the anomalous Bogoliubov terms $b^\dagger d^\dagger$ and db to be absent in $:H_2:$. The mass-gap equation (16) is known to possess one trivial solution $\varphi_{\mathbf{p}} \equiv 0$ and multiple nontrivial solutions [2–7]. For the sake of simplicity, let us assume the existence of just two nontrivial solutions – one describing the vacuum and the other defining one replica (more than one replica will not change the argument).

As soon as the mass-gap equation is solved and a nontrivial chiral angle is found, the Hamiltonian (15) takes a diagonal form,

$$H = E_{\text{vac}} + \sum_{\mathbf{p}, \alpha, s} E_{\mathbf{p}} [b_{\mathbf{p}s}^{\alpha\dagger} b_{\mathbf{p}s}^{\alpha} + d_{\mathbf{p}s}^{\alpha\dagger} d_{\mathbf{p}s}^{\alpha}] + \dots, \quad (17)$$

where $E_{\mathbf{p}}$ is the dressed-quark dispersive law, and the ellipsis stands for the omitted terms responsible for the formation of bound states of quarks. A Fock space can be built on top of the nontrivial vacuum $|0\rangle$ upon the action of the quark creation operators.

As it always happens after a Bogoliubov–Valatin transformation, the new vacuum contains an infinite set of strongly correlated 3P_0 quark-antiquark pairs [12]. The same holds true for the replica $|R\rangle$, so it is not hard to find explicitly the operator which defines a pseudounitary transformation from $|0\rangle$ to $|R\rangle$:

$$|R\rangle = e^{Q-Q^\dagger}|0\rangle, \quad Q^\dagger = \frac{1}{2} \sum_{\mathbf{p}} \Delta\varphi_{\mathbf{p}} C_{\mathbf{p}}^\dagger, \quad (18)$$

where $C_{\mathbf{p}}^\dagger = b_{\mathbf{p}s}^{\alpha\dagger}[(\boldsymbol{\sigma}\hat{\mathbf{p}})i\sigma_2]_{ss'} d_{\mathbf{p}s'}^{\alpha\dagger}$, with σ 's being the 2×2 Pauli matrices, and $\Delta\varphi_{\mathbf{p}}$ being the difference between the vacuum and the replica chiral angles. The operator $C_{\mathbf{p}}^\dagger$ creates a 3P_0 quark-antiquark pair with zero total momentum and the relative three-momentum $2\mathbf{p}$, while the operator $\exp[Q - Q^\dagger]$ creates a strongly correlated cloud of such pairs.

Using the commutation relations for the quark operators b and d , one can readily arrive at Eq. (1) in the form:

$$\langle 0|R\rangle = \exp \left[V \int \frac{d^3p}{(2\pi)^3} \ln \left(\cos^2 \frac{\Delta\varphi_{\mathbf{p}}}{2} \right) \right]. \quad (19)$$

The function $\Delta\varphi_{\mathbf{p}}$ is predominantly nonvanishing at $|\mathbf{p}| \lesssim \Lambda_\chi$, while decreasing fast at larger relative momenta. For this reason, the integral in the exponent of Eq. (19) is $\mathcal{O}(\Lambda_\chi^3)$, and only an overall numerical coefficient of the order of unity depends on the details of the interquark interaction.

This way, the scale of chiral symmetry breaking Λ_χ , initially introduced through the quark kernel $K_{\mu\nu}$, appears naturally in the second-quantised formalism. Thus we have obtained a particular realisation of the physical picture which was described in the previous sections in general terms.

6. Discussion. In this Letter, we have discussed some physical consequences of having more than one realisation of chiral symmetry breaking in QCD. Indeed, given a highly nonlinear nature of the phenomenon of chiral symmetry breaking, the possibility for the mass-gap equation to possess more than one nontrivial solution does not look unnatural – on the contrary, one would need to specially arrange for a nonlinear equation to possess just one solution. In the literature, the presence of multiple solutions to the mass-gap equation was verified in a number of NJL-type models, and the corresponding excited vacuum states were constructed explicitly. Among such states, only the lowest one can be associated with the genuine vacuum of the theory, while the others should be interpreted as some scalar excitations on top of it – we use the term replicas for them. In particular, by putting forward the conjecture that replicas may fill domains in the Universe, we have further explored stability conditions for the size of such domains. It turns out that the allowed domain radius can vary from just a few fermi up to a few kilometres.

The only way for the domain to be detected by an external observer is through its decay to the QCD vacuum, with the release of the vacuum energy in the form of a cloud of hadrons (predominantly pions), which would further annihilate, producing light. Notice however that, due to the very strong correlations between quarks inside the domain, which result in the exponentially small overlap (1) of the replica and the vacuum states, such decays occur quite seldom. And indeed, according to Eq. (3), the probability for a macroscopically large domain to decay per unit time is exponentially suppressed. One is therefore led to conclude that, if such encapsulated domains appeared in the Universe at its early stages, they would have a chance to survive till the present time, remaining however dark to external observers.
